External ventricular drainage (EVD) is a common procedure performed in neurosurgical field. The purpose of this study was to introduce the linear intracranial calcification formed along EVD tract and to investigate its incidence, predisposing factors, and clinical impact. A total of 59 patients who underwent EVD insertion over a 1-year period were included in this study. The clinical factors and radiographic features between the occurrence and the non-occurrence groups were analyzed to investigate the predisposing factors and clinical impact related to the linear intracranial calcification in EVD tract. The linear intracranial calcification following EVD insertion occurred in 7 patients (11.9%). Among various risk factors assessed, only usage of bone dust (p=0.003) had contributed to linear intracranial calcification with statistical significance in univariate logistic regression analysis. Housefield unit (HU) scale was different between calcification (872.57 ± 46.15 HU) and EVD catheter (169.00 ± 61.35 HU). This study indicates that using bone dust for sealing a burr hole is the only predisposing factor for linear intracranial calcification formed in EVD tract.

Keywords: Bone dust, External ventricular drainage, Linear intracranial calcification

Introduction

External ventricular drainage (EVD) is one of the most widely performed neurosurgical procedures. Although it is useful to control increased intracranial pressure or for drainage of intraventricular hemorrhage, there are several complications related to procedure such as infection, hemorrhage and intracranial calcification, rarely. In our

center, by accident, one computed tomography (CT) scan taken after removal of the EVD catheter demonstrated longitudinal radiopaque lesions along EVD catheter tract, which could be considered as torn EVD silicon catheter (Fig. 1). However, the undamaged tip of EVD catheter confirmed at the time of its removal by attending doctor and its different housefield unit (HU) scale from that of the catheter made the lesion diagnosed as not torn catheter, but the linear calcification. Thus, the purpose of this study was to introduce the linear intracranial calcification in EVD tract and to investigate predisposing factors and clinical impact of the calcification.

Fig. 1. Follow-up computed tomography demonstrates linear intracranial calcification following external ventricular drainge on right side. Radiopaque lesion on left side was exteranl ventricular drainge catheter. It is difficult to recognize linear calcification along catheter tract via visual inspection on the CT. It may erroneously lead one to consider torn tip of EVD catheter remained in brain parenchyma.

Materials and Methods

Patients' population

The authors retrospectively reviewed the medical records as well as the pre and postoperative CT scans of the 59 patients who underwent EVD from September 2013 to August 2014. There were 29 male (49%) and 30 (51%) female in this study, ranging in age from 24 to 94 years old (mean ± SD: 61.07 ± 13.67). The patients were divided into two groups according to the occurrence of linear intracranial calcification after EVD removal. The clinical and radiological factors were compared between the occurrence group and the non-occurrence group.

Clinical and radiological evaluations

The occurrence of linear intracranial calcification was defined as longitudinal radiopaque lesions along EVD catheter tract in CT scan and lower HU scale of the lesion than that of EVD catheter. Blood calcium level was categorized into three groups: low (<8.7), normal (8.7-10.4), high (>10.4). Clinical symptoms were quoted from Fahr's syndrome which is characterized by abnormal deposition of calcium in areas of the brain that control movements including basal ganglia, thalamus, dentate nucleus, cerebral cortex, cerebellum, subcortical white matter, and hippocampus [1,2].

Surgical procedure and management

All ventriculostomy were performed by two neurosurgeons in operation room with surgical drape, clearly. Burr hole was made at Kocher's point by using electronic high-speed surgical drill. Bone dust on drilling the bone was collected. Then

dura mater and arachnoid membrane were cut by No.15 blade and coagulated by bipolar coagulation. EVD catheter tip was placed into anterior horn of lateral ventricle and cortex was covered with Surgicel® (Ethicon, North Ryde, NSW, Australia). Neurosurgeon A used the bone dust collected to fill a burr hole for the purpose of preventing sunken deformity of scalp over burr hole site. Neurosurgeon B didn't use the bone dust, but absorbable gelatin sponge (Cutanplast sponge; Cure Sys Ltd, Bucheon-si, South Korea) to fill a burr hole. Any other skills and the type of equipment the two neurosurgeons used were not different from each other. All the patients had pre-operative CT, post-operative CT, post-removal CT and follow up CT, serially. Therefore, those serial CT examinations were compared to identify formation, location and proliferation of linear intracranial calcification in EVD tract.

Statistical analysis

A univariate logistic regression analysis was performed with Fisher's exact test and student's t-test to assess the relationship between each factors and the occurrence of linear intracranial calcification. The statistical significance was set at $p < 0.05$.

Results

Patients' characteristics are summarized in Table 1. Linear intracranial calcification in EVD tract after removal of EVD catheter was found in 7 patients (11.9%). The demographic data was not significantly associated with linear intracranial calcification in EVD tract. Comorbidities, antithrombotics usage and smoking or alcohol consumption were also not related to the occurrence of linear intracranial calcification in EVD tract. Causes of performing EVD were various, but all of them did not have the statistical significance. In operation, the rate of using bone dust in patients with linear intracranial calcification (100%) was higher than that in those without linear intracranial calcification (38.5%) with statistical significance ($p < 0.01$). However, any other operative factors were not related to the occurrence of linear intracranial calcification. Information of 7 patients with linear intracranial calcification was demonstrated in Table 2. Mean duration of EVD was 8.57 ± 5.00 days. Duration of identification of calcification from operation (days) was varied from 1 to 27 (mean: 9.57 ± 8.68 days). Mean HU scale of EVD catheter (872.57 ± 46.15 HU) was higher than that of the calcification (169.00 ± 61.35 HU). It was most important means to differentiate the calcification from EVD catheter. Clinical symptoms associated with linear intracranial calcifications were listed in Table 3. Neurological symptoms like seizure, coma and spasticity were not presented. Dementia was manifested on two patients. However, dementia did not be considered as newly onset clinical symptom associated with linear intracranial calcifications, because it is a common symptom related with stroke attack. Movement disorder like involuntary movement was not presented. Neuropsychiatric features like psychosis were found in one patient, which was just temporary, mild and gradually subsided after several days.

Discussion

External ventricular drainage was first performed as early as 1744 by Claude-Nicholas LeCat [3,4]. Nowaday, it is a well-established procedure in the management of hydrocephalus,

technique, materials used, indication for the procedure [3]. In Korea, because national medical insurance policy does not allow for using a plate for covering a burr hole site, an neurosurgeon in our center used bone dust for covering a burr hole to prevent sunken deformity of scalp over burr hole site by stimulating ossification. However, as one of rare complications, the authors experienced several cases of linear intracranial calcifications along external ventricular drainage tract mimicking torn EVD silicon catheter remained. In this study, its incidence rate is about 11.9%. The authors introduced the linear intracranial calcification in EVD tract and investigated predisposing factors and clinical impact of the calcification. Alorainy [5] suggested that small bone pieces pushed into the brain parenchyma from the calvarium during insertion of the drainage tube might cause small bone fragment in the tract of drain. Findings in one patient of the present study are consistent with the suggestion of Alorainy [5]. The linear calcification adjacent to EVD catheter in the patient was

identified on immediate postoperative CT and the size and shape were not changed on the follow-up CT scan. However, this hypothesis is not a convincing explanation for the other 6 cases and no development of the calcification in the patients disusing bone dust. Linear calcification of these 6 cases were identified on CT scan after 48 hours from operation and proliferated in size and shape. The other pathogenesis of linear intracranial calcification in EVD tract is that bone dust covering a burr-hole after EVD insertion can be pushed into the brain parenchyma and proliferated after EVD catheter removal. According to the report of Thomson *et al* [8], bone dust contains viable osteoblast that are capable of dividing and laying down bone when implanted into vascular tissues. Consistent with the report of Thomson *et al* [8], all 7 cases of linear intracranial calcifications were found in the patients using bone dust. The rate of using bone dust in patients with linear intracranial calcification (100%) was higher than that in those without linear intracranial calcification (38.5%) with statistical significance (p=0.003). In 5 of 7 patients, the calcifications were identified on CT scan examined after removal of EVD catheter. In 1 of remained 2 patients, the calcification was seen on CT scan taken after removal of contralateral EVD catheter and in the other, it was found immediate after ipsilateral EVD catheter insertion. Therefore, the authors suggest that change of pressure and spaces might develop between lateral ventricle and brain cortex after the EVD insertion or at the time the EVD was removed. The pressure change was likely to have bone dust with viable osteoblast sucked into the EVD tract. Calcification was enlarged over time because of viable osteoblast. On the other hand, none of calcification was observed when bond defect was covered with surgicel alone followed by a watertight galeal closure in our study. It is difficult to recognize linear calcification along catheter tract via visual inspection on the CT. It may erroneously lead one to consider torn tip of EVD catheter remained in brain parenchyme. The way to differentiate this lesion from EVD silicon tube is measuring HU scale of the lesion on CT scan. HU scale of the calcification was lower (169.00 ± 61.35 HU) than that of EVD catheter, whereas HU scale of EVD catheter was high (872.57 ± 46.15 HU). All of 7 patients have had no newly onset, long lasting clinical symptoms or signs associated with linear intracranial calcification. Although neuropsychiatric features like psychosis were found in one patient, it was not considered as being related to calcification due to its temporary development. Surgical removal or particular medication is unnecessary so far. However, it is uncertain because of short follow-up period. Therefore, the clinical and radiological long term surveillance may be needed for the patients who have linear intracranial calcification in EVD tract, continuously.

Conclusion

The present study suggested that the cause of linear intracranial calcification mimic torn EVD catheter in EVD tract is bone dust covering a burr-hole after EVD insertion. Therefore, to prevent these complications, bone dust should be disused and national health insurance service should consider covering price of plate for sealing a burr hole. It is important to differentiate linear calcification from EVD tube silicon and long term follow-up is necessary to assess a clinical impact of linear intracranial calcification in EVD tract.
